

GEOLOGIC COLUMN AND UNIT DESCRIPTIONS

AGE	ROCK UNIT	LITHOLOGY; THICKNESS WHERE KNOWN	UNIT DESCRIPTION	ECONOMIC VALUE																																																																																																																																																																			
QUATERNARY	Alluvium	Sand, clay and gravel; thickness less than 10 meters	Alluvium, consisting of sand, clay and gravel, is distributed in the drainage basins of the Hai-la-erh Ho (海拉爾河), the Argun River and their tributaries, covering flood plains and low terrace remnants. Regions of alluvial deposits are characterized by numerous plays and swamps. Some of the inland lakes have no outlets, resulting in saline brackish deposits. Recent sand dunes are found in places. Alluvium can be divided into Qds and Qes. Qds consists chiefly of aeolian dune sand of Pleistocene to Recent age, and is sporadically distributed in the southern part of the map area. The dune sand is yellowish brown, yellowish gray, or light brown fine-grained quartz sand, and is 30 m thick on a hill east of Hailar. Qes, consisting of sand, clay and gravel, is a Pleistocene deposit of aeolian, fluvial and lacustrine origin, known as the Hailar formation (海拉爾組). Eight drillholes in the vicinity of Hailar revealed the following sequence in descending order (depth in meters, drillhole numbers refer to sites numbered on map):

TERTIARY	Neogene basalt	Olivine-sugite basalt	The Neogene basalt is dark gray or black massive cryptocrystalline trap type basalt, rarely containing olivine and sugite phenocrysts.	Building stone Neogene basalt in the cliff 6 km north of Hailar can be used as building stone.																																																																																																																																																																			
	Cretaceous andesite	Biotite andesite and dacite	Cretaceous andesite includes two lithologic types, biotite andesite and dacite. Biotite andesite is light to dark green, massive, compact and vesicular, showing a flow structure. The rock resting on the Cretaceous rhyolite (T4) near Ts-liang-shan (亮上) is grayish green and shows a rhyolitic structure, and that near T'ou-chan (頭山) is dark brown and contains visible phenocrysts of biotite and feldspar. The rock overlain by the rhyolite near K'u-k'u-hi (庫庫黑) in the south-central part of the map is a light gray, brown or dark brown, massive dacite, having phenocrysts of quartz, plagioclase and biotite. It is probably an acidic type of biotite andesite lava. The rock in the hill west of Ts-liang-shan near the west edge of the map is an agglomeratic dacite.																																																																																																																																																																				
	Cretaceous rhyolite	Rhyolite and cryptocrystalline rhyolite	The Cretaceous rhyolite consists of assemblage of rhyolite proper and cryptocrystalline rhyolite. It is locally associated with obsidian in the vicinity of Chiang-shing Shan (昌興山) along the Mo-erh-ko Ho, and with trachyte in the vicinity of Osh Pass north of Kan-ching-tzu. The rock near Garosu shows a flow structure and rarely a spherulitic structure.																																																																																																																																																																				
	Lower Cretaceous formation	Conglomerate, sandstone, shale, tuff and coal; thickness unknown	The Lower Cretaceous formation is exposed in the following four places: (1) The formation on the north bank of the Hai-la-erh Ho, 1.5 km northeast of T'ou-kang (頭崗) rests on the pre-Jurassic granite (g <sub>1</sub> ). It consists chiefly of conglomerate, thinly intercalated with sandstone and shale. Pebbles of the conglomerate are quartz porphyry and Paleozoic rocks, 1 to 10 cm in diameter and are cemented by medium-grained sand. The shale is gray or blue, and the sandstone is light gray and medium- to fine-grained. The formation strikes N 20° W, and dips 50° W to 20° E. The western boundary is faulted against gneissic granite. (2) The formation in the cliff 20 km south of Hailar is covered by the Pleistocene deposit. It consists of sandstone and conglomerate containing pebbles of quartz porphyry. It strikes N 20° - 40° E and dips 20° - 30° SE. (3) The formation on the hill 15 km north of K'u-k'u-hi is interbedded in the rhyolite flow. It consists of sandstone, shale, conglomerate and tuff, having the same dip and strike as the schistosity of the rhyolite flow. (4) The formation near a pass 23 km northwest of T'ou-chan consists essentially of sandstone. It is overlain by the Cretaceous andesite (M <sub>6a</sub> ), and strikes N 20° E, dipping 50° E.																																																																																																																																																																				
	Diorite		Diorite crops out in a cliff 5 km northwest of Hailar. It is probably a facies of the Cretaceous granite.																																																																																																																																																																				
	Cretaceous granite	Biotite granite	Cretaceous granite is exposed in the northeastern part of the map area. It is composed chiefly of biotite granite intruding the Lower Paleozoic formation.																																																																																																																																																																				
	Jurassic formation	Sandstone, quartzite, conglomerate, shale and tuff; thickness unknown	The Jurassic formation is exposed on the hills north of Hailar. It strikes N 50° - 55° W and dips 5° - 15° SW. The stratigraphic sequence in descending order is as follows: (1) light yellow coarse-grained sandstone, (2) quartzite locally associated with conglomerate, (3) light gray sandstone intercalated with black shale which yields plant fossils such as <i>Bolites williamsoni</i> (Broogn.) and <i>Pityophyllum</i> cf. <i>indistinctum</i> (Wathorst), and (4) grayish green tuff. On the basis of the fossils, the formation is assigned to Upper Jurassic. The tuffaceous sandstone and shale exposed in the cliff 4 km northeast of Hailar corresponds to the Jurassic formation. The formation near Shierutai in the northeastern part of the map area consists of sandstone, siliceous slate, tuff and conglomerate containing pebbles of Paleozoic rocks. The formation is intruded by the Cretaceous granite and shows a folding structure.	Building stone Shale interbedded in the Jurassic formation exposed in the hill 2 km north of Hailar was formerly quarried, but the rock is too fragile to be used as building stone.																																																																																																																																																																			
	Jurassic(?) andesite	Cryptocrystalline andesite	Jurassic(?) andesite occurs as flows resting on the Jurassic volcanic complex (M <sub>1v</sub> ). It is exposed in the following three places: (1) The andesite in the hills such as Cheng-ta-ch'i Shan (程塔奇山) along the Argun River is black, compact and cryptocrystalline, having no visible phenocrysts. Under a microscope, the groundmass containing hornblende phenocrysts shows an andesitic structure. (2) The rock at Osh Pass 7 km south of Garosu is a grayish purple cryptocrystalline rhyolitic andesite having lenticular vesicles filled with calcite. (3) Andesite of probable Jurassic age crops out in a small area 8 km north-northeast of Hailar.	Fluorite Quartz veins in the quartz porphyry and the Jurassic andesite near Hai-san contain fluorite which is of little economic value due to small reserves and difficult access.																																																																																																																																																																			
	Jurassic volcanic complex (greenstone complex)	Diorite porphyry, andesite porphyry, diabase porphyry, dolerite, pyroxite, breccia, tuff and sandstone; thickness more than 500 m	The Jurassic volcanic complex, or greenstone complex, consists of an assemblage of dark greenish igneous intrusives and extrusives. It is exposed in the following three places: (1) The complex near Botogochi along the Argun River consists of diorite porphyry, andesite porphyry, diabase porphyry, dolerite, volcanic breccia, tuff and sandstone. (2) The complex in the vicinity of Hailar consists of reddish hornblende diorite porphyry. (3) The complex near Haiminshutan in the U.S.S.R. is assigned to Upper Jurassic undifferentiated effusives (MALYKIN, 1955). It rests on the pre-Jurassic granite (g <sub>1</sub> ) and is overlain by the Lower Cretaceous coal-bearing formation (M <sub>1</sub> ).																																																																																																																																																																				
	Quartz porphyry		Quartz porphyry is exposed on the hills between the Argun River and the Hailar River. It is probably a marginal facies of the pre-Jurassic granite. The quartz porphyry in the northeastern corner of the map area is probably Cretaceous in age. Some agate occurs in a hill 8 km southeast of Hai-san.																																																																																																																																																																				
Pre-Jurassic granite	Biotite granite, hornblende granite, gneissic granite, diorite and aplite	The pre-Jurassic granite is exposed in the northeastern part of the map area. It intruded the Lower Paleozoic formation and contact-metamorphosed it. It consists chiefly of biotite granite associated with hornblende granite, gneissic granite, diorite, and aplite in the Manchurian side. The granite in the U.S.S.R. is defined by Soviet geologists as Paleozoic acidic intrusives, such as granite, granodiorite and quartz diorite.																																																																																																																																																																					
PALEOZOIC	Lower(?) Paleozoic formation	Shale, clay slate, phyllite, schist, gneiss and hornfels; thickness unknown	The Lower(?) Paleozoic formation in Manchuria consists of a complicated assemblage of shale, clay slate, phyllite, schist, gneiss and hornfels. These rocks were probably metamorphosed from the Paleozoic sandstone and slate due to the granite intrusion. The formation does not contain calcareous rocks or fossils that help determine the geologic age. The formation in Manchuria is known in the following four places: (1) The formation in the cliff 8 km northeast of Ts-liang-shan consists of dark green hornblende-biotite schist and gray mica schist. Its schistosity strikes N 45° - 55° E and dips 25° - 60° SE. It was probably derived from clay slate by the contact-metamorphism of granite. (2) The formation near Shierutai consists of black clay slate, phyllite and dark gray sandy slate. It strikes N 40° - 45° E and dips almost vertically to north or south, forming complicated folds. (3) The formation in the hill 3 km south of Hai-san consists chiefly of hornfels and injection gneiss derived from sedimentary rocks due to the intrusion of biotite granite. (4) The formation along the cliff 3 to 13 km northeast of Ts-liang-shan (程塔奇山) consists of siliceous clay slate and biotite metagneiss. It strikes N 60° E and dips 30° - 40° SE. It is intruded by the pre-Jurassic granite and is overlain by the Jurassic volcanic complex. The siliceous clay slate is yellowish gray and compact, showing marked joints, and locally contains unmetamorphosed fresh shale. The gneiss interbedded in the slate occurs near the contact with granite. It consists of an alternation of biotite, light yellow feldspar, and thin layers of siliceous rocks showing a banded structure. It was metamorphosed from siliceous clay slate. The formation in the northwestern corner of the map area was assigned to Lower Cambrian by the Soviet geologists, but available data are few.																																																																																																																																																																				
	Granite gneiss	Granite gneiss and injection gneiss	A granite gneiss in the cliff 8 km northeast of Ts-liang-shan surrounds the Lower Paleozoic schist. An injection gneiss exposed near Hai-san in the boundary zone between hornfels and granite shows a banded structure. Both were probably metamorphosed from the Lower Paleozoic formation by granite intrusion.	Building stone Granite gneiss exposed in the cliff 8 km northeast of Ts-liang-shan can be used as building stone. Because of its schistosity it is easily quarried.																																																																																																																																																																			

GROUND WATER

The map area is situated in the Hailuier-shih-Gobi desert, and ground water occurring in the Quaternary deposits is more or less saline.

(1) Hailar: Three aquifers are found in Hailar town, occurring at the depths of 2 to 3 m, 20 to 30 m and 50 m respectively. Water of the first aquifer, which consists of thin porous sand and gravel beds, is not good quality, but water of the second aquifer, which consists of fine sand, is generally fit to drink.

(2) Flood plain south of Hailar: Aquifers of this area are as follows:  
 Hai-tun (海屯), east end of town ..... 2.2 m (drinkable)  
 Hai-tun, central street ..... 3.0 m (drinkable)  
 Wu-chien-fang (五前房) ..... 2.7 m (not drinkable)  
 Wu-chien-fang ..... 2.5 m (not drinkable)  
 Lu-chien-fang (六前房) ..... 2.4 m (drinkable)  
 Yao-lu-tzu ..... 1.9 m (drinkable)  
 1.5 km north of Yao-lu-tzu ..... 2.8 m (drinkable)

(3) Hill south of the Hailar River: Aquifers occur at depths from 2.7 to 17.4 m. Water is thought to have permeated from the river. A shallow aquifer is exposed on the shore of a lake near Milte-shan.

(4) Hill eastern of Hailar: A drillhole 5 km east of Hailar revealed an aquifer at a depth of 26.8 m.

(5) Hill northern of Hailar: A drillhole 6 at Ts-liang-shang, 17 km north of Hailar, revealed an aquifer at the depth of 3 m.

(6) Neighborhood of Osh Pass between Kan-ching-tzu and Garosu: An aquifer occurs at the depth of 2 to 2.5 m. Water is abundant and good in quality.

Several springs of good water are found along the valley of So-erh-po-k'o-kai (索爾河).
